TITLE: Dynamic Gain Equalization S for MAN/WAN using WDMA  
and Semiconductor Optical Amplifier

## TBTX:

This document contains drawings, figures, and/or symbols that will not appear on line. Request for complete article. - Disclosed is a dynamic gain equalization scheme using planar gratings and semiconductor optical amplifiers to overcome the near-far problem in transmission spectra present in a local area network or wide area network. The potential near-far problem where signals originating from different locations experience different attenuation. Furthermore, fibers in such a network also have nonflat gain spectra. Different wavelengths experience different gain even though they travel through the same physical path. The existing studies on gain equalization have focused on equalizing the nonflat gain spectra of the optical amplifiers. Gain equalization using fiber gratings and a 3+ fiber amplifier was proposed in [1] where a large equalization bandwidth is achieved. Dynamic gain equalization is achieved by adjusting the gain dynamically. Two-stage gain equalization was proposed in [2] to equalize the gain spectra of pump power) the optical signal channels in a WDMA system. This scheme has a limited equalized bandwidth of 80 nm. Dynamic gain equalization can also be achieved through controlling the gain spectra of the optical filters. In a dynamic equalized 29-channel WDM system, dynamic gain equalization using a Mach-Zehnder Interferometer (MZI) and a tunable filter (AOTF) has also been proposed. The AOTF has a tunable filter for a very wide transmission spectrum for a very wide transmission spectrum. The injection of multiple RF frequencies into the transmission characteristic magnifies the gain equalization. The essence of this scheme, however, is limited by the resolution of an AOTF. Fig. 1 shows the proposed dynamic gain equalization scheme. The incoming multiple optical signals are demultiplexed into multiple wavelength channels, each of which is responsible for the gain adjustment. The gain-equalized signals are then multiplexed back into a single output. - The essence of this scheme is the dynamic adjustment of the gain spectra of the optical amplifier through modifying the injection

The incoming multiple optical signals are demultiplexed into multiple wavelength channels, each of which is responsible for the gain adjustment. The gain-equalized signals are then multiplexed back into a single output. - The essence of this scheme is the dynamic adjustment of the gain spectra of the optical amplifier through modifying the injection

Furthermore, the gain of the optical amplifier is dynamically adjusted to achieve a constant output of the optical amplifier of the incoming optical power. This is achieved by a close loop monitor (2), which measures the voltage drop by using a low-pass filter. The resulting value is compared with the desired value and used to correct the gain of the amplifier. This approach is justifiably used because only the gain needs to be controlled in the amplifier. The wide equalization approach is the wide equalization grating and semiconductor amplifier (high resolution achieved by the small spacing). Furthermore, crosstalk is virtually nonexistent in this system as the signal is being amplified. - The power consumption required for amplification necessitate the use of a control wavelength multiplexer can be realized with optical grating and a planar waveguide gratings can be employed but it is improved to be practical. In particular the planar waveguide grating can avoid beam diffraction (2) semiconductor material which can be used with optical amplifiers. The optical amplifier can be realized with an array of semiconductor material such as wide bandwidth multiple semiconductor material. Similar to the wavelength multiplexer, the demultiplexer can be realized with optical grating or waveguide grating. It should be noted that the multiplexer, optical amplifier, and demultiplexer can be totally integrated by using semiconductor material. Refer to P. R. Morkel and D. N.
